Adaptive Stabilization of Electro-dynamical Transducers

Wolfgang Klippel, Klippel GmbH, Dresden, Germany

A new control technique for electro-dynamical transducer is presented which stabilizes the voice coil position, compensates for nonlinear distortion and generates a desired transfer response by preprocessing the electrical input signal. The control law is derived from transducer modeling using lumped elements and identifies all free parameters of the model by monitoring the electrical signals at the transducer terminals. The control system stays operative for any stimulus including music and other audio signals. The active stabilization is important for small loudspeakers generating the acoustical output at maximum efficiency.

0 INTRODUCTION

Electro-dynamical transducers generating the required acoustical output at high efficiency, low cost, small size and minimum weight are strongly nonlinear systems causing not only harmonic and intermodulation distortion but also generating a DC-displacement which drives the coil away from the rest position [1].

Fig. 1. Amplitude of the AC and DC components of the voice coil displacement for a sinusoidal stimulus above resonance

A well-made transducer having a high efficient motor structure may also bifurcate into two states with a positive or negative DC displacement if the stiffness is too low or the suspension becomes softer over time due to aging of the material over time or climate impact. This instability inherent in the electro-dynamical transduction principle is a major concern in the development of moving coil loudspeaker and can generate a DC-component which exceeds the RMS-value of the AC-component as shown in Fig. 1. The transducer engineer can cope with the instability by using a relatively stiff mechanical suspension (spider, surround) with progressive nonlinearity of stiffness characteristic $K_m(x)$ which increases the resonance frequency and reduces the maximal peak displacement $X_{\text{max}}$.

This paper develops a new concept for stabilizing such transducers actively by digital signal processing.

1 CONTROL WITHOUT STABILIZATION

Before presenting the new approach the basic principle of the transducer-related control technique [3] will be discussed. The basic principle is illustrated as a signal flow chart in Fig. 2.

Fig. 2. Adaptive control system without stabilization

A digital signal processor generates from an audio input signal $z(t)$ a control output signal $w(t)$ which is supplied via a power amplifier to the terminals of a woofer, tweeter, microspeaker or any other electro-dynamical transducer. The power amplifier has usually a low output impedance and uses a high-pass to avoid driving the transducer with a DC component. Based on the voltage $u(t)$ and the measured input current $i(t)$ a detector identifies the free parameters of a transducer model summarized in vector $P$. The parameter are assumed as time-invariant over a limited period ($T < 1 \text{ min}$) but depend on the ambient climate condition, aging of the transducer materials and other changes of the mechanical or acoustical load driven by the transducer [2]. To cope with these parameter variations the detector generates updates of vector $P[n]$ which are fed back to the audio signal processing. Contrary to the negative feed-back of state signals the parameter feed-back can cope with any latency caused by DAC, ADC and other digital signal processing. It is also useful to store the vector $P[n]$ in a memory $M$ and to use old values as initial parameters after restarting the adaptive control system.
the rest position, the mechanical resistance \(R_m\) and the total mechanical impedance

\[
Z_m(s) = \frac{\sum_{i=0}^M a_i s^i}{\sum_{i=0}^N c_i s^i}
\]

describing the effect of the mechanical stiffness \(K_m(x=0)\) at the rest position, the mechanical resistance \(R_m\), the moving mass \(M_m\) and the load impedance \(Z_{load}(s)\) of the coupled acoustical and mechanical system. The order \(M\) describes the number of poles and zeroes in the rational transfer function \(Z_m(s)\). A transducer mounted in a sealed enclosure can be modeled by a second-order function \(Z_m(s)\) while a vented box requires a higher-order system, which makes the identification of the linear parameters more difficult.

### 1.2. Parameter identification

The free parameters of the electrical equivalent model summarized in the parameter vector

\[
P = [P_1 \ldots P_j \ldots P_J]^T
\]

can be identified from the voltage and current monitored at the terminals reproducing an audio signal (e.g. music) by the transducer. The system identification is based on minimizing an error signal such as the difference

\[
e(t) = u'(t) - u(t)
\]

between voltage \(u'(t)\) predicted by the model in (1) and the measured voltage \(u(t)\). The optimal parameter vector \(P\) can be determined by searching for the minimum of the mean squared error

\[
P = \arg\min_{\hat{P}} \left\{ E\left\{ e(t)^2 \right\} \right\}
\]

corresponding to the requirement

\[
\frac{\partial E[e(t)^2]}{\partial P_j} = 2e(t) \frac{\partial e(t)}{\partial P_j} = 2e(t) \frac{\partial u'(t)}{\partial P_j} = 0 \quad j=1,\ldots,J
\]

giving the Wiener-Hopf-equation

\[
P = R^{-1}Y = \left[E(G(t)G(t)^*) \right]^{-1} E(u(t)G(t))
\]

with the expectation value \(E[\cdot] \ldots \) and the gradient vector \(G(t)\)

\[
G(t) = \left[ \frac{\partial u'(t)}{\partial P_1} \ldots \frac{\partial u'(t)}{\partial P_j} \ldots \frac{\partial u'(t)}{\partial P_J} \right]
\]

The gradient vector \(G(t)\) is generated in the gradient calculator GC in Fig. 4 based on the state vector \(S(t)\) generated by a transducer model in accordance with (1).

Alternatively the optimal parameter vector \(P[n] = P[n-1] + \mu(t) e(t) G(t)\)

\[
P[n] = P[n-1] + \mu(t) e(t) G(t)
\]

can be estimated iteratively by using the stochastic gradient method (LMS-algorithm) with the learning speed matrix \(\mu(t)\) as shown in Fig. 4.

![Fig. 3. Equivalent circuit of the electro-dynamical transducer](image)

![Fig. 4. Detector estimating the parameter vector P based on monitored voltage u and current i](image)
noise signal. Furthermore, a badly conditioned matrix \( R \) reduces the learning speed and the accuracy of the parameter measurement process. Therefore, a supervisory system DS shown in Fig. 4 sets at least one learning speed parameter in \( P(t) \) to zero if the rank \( \text{rk}(R) \) of the matrix \( R \) is smaller than the number \( J \) of free parameters in vector \( P \).

### 1.3 Audio signal processing

The identified parameter vector \( P \) is used for the processing of the audio signal as shown in Fig. 5. A state estimator generates a state vector \( S_p \) which comprises the voice coil displacement

\[
x(t) = L^{-1}[H_s(s)]y(t)
\]

(13)

Corresponding to the target transfer function \( H_s(s) \) of the linearized overall system and the nonlinear input current \( i \) predicted by (1).

![Fig. 5. Processing of the audio signal with mechanical protection and feed-forward linearization (mirror filter).](image)

A mechanical protection system attenuates the input signal \( z(t) \) if the predicted absolute value of the voice coil displacement \( |x(t)| \) exceeds a permissible limit value \( x_{\text{max}} \). The parameter and state information are also used in the control law

\[
w(t) = \alpha(P,S_p)\beta(P,S_p)y(t) + P(t)
\]

(14)

to compensate the nonlinear distortion and synthesize the desired overall transfer behavior [4-6]. The prediction of the state vector \( S_p \) and the generation of the both control gain \( \alpha(P,S_p) \) and the control additive \( \beta(P,S_p) \) exploits the nonlinear transducer model in (1) as described in [11].

### 1.4 Adaptive control limitations

The control and protection system is based on a transducer model which neglects creep and other viscoelastic behavior of the suspension [12][13]. The creep effect reduces the stiffness at low frequencies and generates a higher value of the DC displacement than predicted by (1). A similar problem occurs when the transducer is operated in an enclosure which is sufficiently sealed for audio frequencies. A small leakage in the enclosure required to compensate for static air pressure variations will reduce the stiffness of the enclosed air volume at very low frequencies. Thus, the DC displacement is significantly higher than predicted by the total stiffness found at the resonance frequency. Extended models developed for viscoelastic behavior of the mechanical suspension and for leaky enclosures are less useful for adaptive control because the accurate identification of the model parameters requires a mechanical sensor which measures displacement at low frequencies. This information cannot be derived from electro-motive force (EMF) found in electrical signals at the transducer terminals.

A further disadvantage of the known control technique is that the adaptive parameter estimation requires a persistent excitation of the transducer. For example, the parameters of a transducer cannot be identified with a single tone stimulus while generating a high DC displacement as shown in Fig. 1.

### 2 ACTIVE TRANSDUCER STABILIZATION

To cope with the unknown voice coil position in the adaptive control system an additional variable \( x_{\text{off}}(t) \) is introduced in the nonlinear parameters

\[
B(x) = \sum_{i=1}^{N} b_i (x + x_{\text{off}}(t))
\]

\[
K_{\text{off}}(x) = K_{\text{off}}(0) = \sum_{i=1}^{N} k_i (x + x_{\text{off}}(t))
\]

\[
L(x) = \sum_{i=1}^{N} f_i (x + x_{\text{off}}(t))
\]

(15)

The offset \( x_{\text{off}}(t) \) may be considered as a time-variant parameter depending on the interactions between transducer nonlinearities and stimulus, viscoelastic behavior of the suspension, gravity and other external influences. The offset \( x_{\text{off}}(t) \) may be also interpreted as a state variable which comprises only low frequency components far below the audio band. By introducing the offset \( x_{\text{off}}(t) \) the time variance of the coefficients \( b_i, k_i \) and \( f_i \) in (15) can be reduced.

![Fig. 6. Control System with stabilization of voice coil position](image)

### 1.5 Voice coil offset identification

The detector has to identify the coil offset \( x_{\text{off}}(t) \) in the back-EMF at the transducer terminals by exploiting the nonlinear distortion generated in the audio band. The instantaneous
The detector as shown in Fig. 7 uses two transducer models according to (1) and (15). The first model describes the long-term behavior of the loudspeaker where the expectation value $E(x_{off}(t))=0$. Thus, the identification of parameter vector $P$ corresponds to the conventional approach shown in Fig. 4. The second model considers the instantaneous coil offset and generates a second error signal $e_2(t)$ which is used in a second LMS algorithm

$$x_{off}(t) = x_{off}(t - \Delta t) + \mu_{off} e_2(t) G_{off}(t)$$

with the gradient

$$G_{off}(t) = \frac{\partial e_2(t)}{\partial x_{off}}$$

$$= \frac{\partial e_2(t)}{\partial x_{off}} + \frac{\partial x_{off}}{\partial x_{off}} \frac{\partial y_{off}(t)}{\partial x_{off}} + \frac{\partial e_2(t)}{\partial x_{off}} \frac{\partial x_{off}}{\partial x_{off}}$$

generated by the gradient calculator GOC from the state vector $S_2$ provided by the second model. The constant learning parameter $\mu_{off}$ permanently enables learning the offset variable $x_{off}(t)$ for any stimulus (including a single tone) supplied to the loudspeaker. The adaptive estimation of the offset variable $x_{off}(t)$ only stagnates if the stimulus generates no displacement of the voice coil.

If the stimulus $z(t)$ provides persistent excitation of the transducer to identify all parameters $b_i$, $k_i$ and $l_i$ in (15), the parameter vector $P$ will represent the voice coil position, and the offset variable $x_{off}(t)$ becomes zero eventually. Therefore only the parameter vector $P$ will be stored in the memory $M$ and used with $x_{off}(t)=0$ as initial values after restarting the control system.

1.6 Audio processing with stabilization

The state estimator as shown in Fig. 8 and the control law

$$u(t) = \alpha(P, S_2, x_{off}) [y(t) + \beta(P, S_2, x_{off})]$$

consider the instantaneous voice coil offset $x_{off}(t)$ in the non-linear parameter definition (15). The mechanical protection system compares the total displacement $|y(t) + x_{off}(t)|$ with the permissible limit value $x_{max}$ to detect a mechanical overload of the transducer and to attenuate the input signal in time. The instantaneous offset $x_{off}(t)$ may reduce the permissible peak or bottom value of the AC signal $x(t)$ to avoid voice coil bottoming or irregular operation generating impulsive distortion commonly called “rub and buzz”.

The new concept of active stabilization of electro-dynamical transducers exploits information from transducer modeling. All free parameters in this model and uncertainties due to viscoelastic behavior and external influences can be identified by monitoring electrical signals at the terminals only. There is no need to measure the absolute position of the voice coil by using a mechanical sensor such as a laser triangulation sensor. There are no additional hardware requirements to ensure reliable protection and linearization of the transducer. If a DC-coupled power amplifier is used in the application, an offset compensator as shown in Fig. 8 detects the symmetry point $x_{sym}$ in the nonlinear force factor characteristic $Bl(x)$ and synthesizes a DC signal $z_{off}$ which moves the coil’s rest position to the symmetry position $x_{sym}$, ensuring highest efficiency and minimum distortion.

3 Practical Evaluation

The new control technique has been implemented in a microcontroller based on ARM 4 architecture connected via a DAC to an AC-coupled power amplifier. A conventional high-pass
was required in the analogue path because the available hard-
wire components generated an unwanted DC offset in the
output voltage under long-term operation.
Due to the hardware limitation, the new control technique
was used to identify the instantaneous offset $x_{off}$ and for ad-
justing the protection and linearization subsystems in the
feed-forward control only. The generation of a DC signal $z_{off}$
to compensate actively for the offset was disabled in all fol-
lowing experiments.

**Fig. 9.** Minimum and maximum values of the voice coil displace-
ment (thin and dashed lines) and the instantaneous voice coil offset
$x_{off}$ (solid line) identified by using voltage and current monitoring
versus time while reproducing various stimuli.

**Fehler! Verweisquelle konnte nicht gefunden werden.** shows the peak and bottom values of the voice coil displace-
ment versus time as thin and dashed lines for different stim-
uli. The offset $x_{off}$ shown as a solid line was permanently
identified even if the stimulus provides no persistent excita-
tion for the estimation of the parameter vector $P$.

**Fig. 10.** Used working range of the nonlinear force factor charac-
teristic $B_l(x)$ represented as a solid line in comparison to the permis-
sible working range (dashed line) for a sinusoidal stimulus at in-
stance $t_1$ as shown in **Fig. 9**.

**Fehler! Verweisquelle konnte nicht gefunden werden.** shows the used working range in the nonlinear force factor
characteristic $B_l(x)$ between the instantaneous peak and bot-
tom values as a solid line and the instantaneous offset $x_{off}$ as
a vertical line at time instance $t_1$ corresponding to **Fehler!
Verweisquelle konnte nicht gefunden werden.** Although
the offset is negligible the asymmetrical shape of the $B_l(x)$
curve will generate significant 2nd-order distortion.

**Fig. 11.** Used working range of the nonlinear force factor charac-
teristic $B_l(x)$ represented as a solid line in comparison to the permis-
sible working range (dashed line) for a sinusoidal stimulus at in-
stance $t_2$ as shown in **Fig. 9**.

At a later time instance $t_2$ in **Fig. 9** the detector identifies a
higher positive value of the offset $x_{off}$ which moves the work-
ing point towards the maximum of the $B_l(x)$ curve reducing
the asymmetry of the force factor as seen by the coil. Thus,
the offset $x_{off}$ depends on the interaction between the woofer
and the properties of the stimulus and has a major impact on
the optimal control of the woofer.

**Fig. 12.** Relative 2nd-order harmonic distortion of the loudspeaker
output without control (thin line), with non-adaptive control with
fixed parameters (dashed line) and adaptive control with offset com-
ensation (solid line).

**Fig. 12** shows the active linearization a woofer for a sinusoi-
dal stimulus. This signal is a very critical signal because it
generates at low frequencies $(f < f_s)$ high voice coil displace-
ment but provides no persistent excitation for the identifica-
tion of other loudspeaker parameters. Thus the adaptive
identification of the parameter vector $P$ is temporarily disa-
bled and previous estimates $P[i]=P[i-1]$ are used for the pre-
processing of the audio signal. Apparently the synthesized 2nd
order harmonic distortion do not match the distortion gener-
ated by the woofer and the compensation fails and the non-
adaptive control produces more distortion in the acoustic out-
put. The new adaptive control which provides the offset $x_{off}$
for any input signal which ensures optimal performance.
While the 2nd-order harmonic distortion are sensitive symptom for any asymmetry in the curve shape of the nonlinear parameters and the influence of a DC component generated dynamically by the loudspeaker itself, the 3rd-order distortion are more related with symmetry of the nonlinear characteristics limited by geometrical constraints in the design of the motor and suspension. Fig. 13 shows a significant reduction of the 3rd-order harmonics which is almost independent of the offset $x_{off}$.

4 CONCLUSION

Active voice coil position stabilization is a fundamental requirement for all control objectives such as mechanical protection, linearization and equalization of the transducer. For example, a significant DC component as shown in Fig. 1 reduces the maximum amplitude of the AC component by 6 dB where bottoming of the voice coil at the back plate occurs. The moving coil transducer's tendency to generate DC and unstable rest position increases in smaller loudspeakers, which generate sound with less hardware resources and energy. A nonlinear motor structure optimized for highest force factor $B_l(x=0)$ at the rest position $x=0$ provides maximum overall efficiency for common audio signals having bell-shaped probability density function $pdf(x)$ of the voice coil displacement. Such a nonlinear but efficient motor structure can be combined with a soft mechanical suspension resulting in a lower resonance frequency and more low frequency displacement. While beneficial for most applications, such a transducer requires active stabilization to cope with the DC component generated dynamically by the transducer. A digital amplifiers combining amplification with digital-analogue conversion is beneficial for transferring the control input containing a DC compensation signal at sufficient accuracy and robustness to the speaker terminals and to ensure that the coil’s rest position stays at the $B_l(x)$ maximum over the entire life time of the product.

The adaptive control algorithm presented in this paper has been illustrated on a moving coil transducer but the same approach can also be applied to other transduction principles such as the balance armature transducer used in hearing aids and in-ear phones.
